

Title: What is the probability that SHFs have slowly unwound their positions in dark pools these past 9 months and that is why DRS'ing is finally gaining traction?

This question is mainly for those that follow the volume (especially on dark pools) religiously, and all the different estimates of SI%.

DRSing has been known for many months but has only now caught a lot of traction and seems to have little resistance. So what is the probability, based on volume since January, and the SI% estimates (e.g. Google surveys), that SHFs have successfully unwound positions to below 100% SI? Has anyone worked on these numbers?
